# Electronic properties of TlFe2Se2 using density functional theory

Doping and anion height are found to drastically affect the electronic structures of superconductors [1-2]. In this study, we investigated the composition-dependence of the electronic properties of the newly discovered intercalated $TlFe_2Se_2$ superconductor using density functional theory. We calculated the electronic structures of $Tl_xFe_2Se_2$ with various Tl concentrations ($x$ = 1.00, 0.75 and 0.50) using a 2 x 2 x 1 supercell. Fractional coordinate $z_{Se}$ of Se which essentially controls the anion height are taken from "relaxed"nonmagnetic and magnetic configurations of $TlFe_2Se_2$ which have values of $z_{Se}$ = 0.341 Å and 0.348 Å, respectively. We also used the experimental value of $z_{Se}$ = 0.357 Å taken from [3], which is higher than the simulated ones. We also added a hypothetical value of $z_{Se}$ = 0.364 Å which is the highest among the fractional coordinate values used. All calculations of the electronic structures are done using QUANTUM ESPRESSO [4]. Generalized gradient approximation of Perdew-Burke-Ernzerhof [5] is used for exchange-correlation potentials.

The density of states (DOS) for various Tl content has shown metallic properties where states near the Fermi energy ($E_F$) are mostly from Fe-$d$ states. This is consistent with the typical features of iron-based superconductors. For various fractional coordinates, $z_{Se}$, the DOS have also shown similar characteristics. Band structure calculations on the other hand revealed different results. For $x$ = 1.00, no pocket is found around the zone center (Γ point) of the First Brillouin zone. For $x$ = 0.75 and 0.50 on the other hand, hole-like pockets are being observed around the Γ point which is typical of Fe-based superconductors. The appearance of the hole-like pockets might be due to the shifting of the $E_F$ towards lower energy when Tl content is reduced. This indicates a possible doping effect in this material (i.e. hole doping).

Furthermore, we also studied the possible three dimensionality of $Tl_xFe_2Se_2$ with various Tl content by observing the Z point of the first Brillouin zone. As Tl content is reduced, a shift of bands is observed towards higher energies which resulted to an appearance of a shallow electron-like pocket around the Z point when $x$ = 0.75. The electron-like pocket is mainly of Fe-$d_{xz}$+$d_{yz}$ character. This is not consistent though with the experiments where the observed electron-like pocket has Fe-$d_{xy}$+Se-$p_z$ character [6]. Looking at the band structure calculations for various $z_{Se}$, the electron-like band found around the Z-point above $E_F$ for $z_{Se}$ = 0.341 Å seems to shift towards lower energies as the $z_{Se}$ increases, which eventually crossed the $E_F$ for $z_{Se}$ = 0.357 Å. This electron-like pocket is now consistent with the experimental results where the orbital character is found to be of Fe-$d_{xy}$+Se-$p_z$. Increasing further the $z_{Se}$ to 0.364 Å, the bands split and a hole-like band is formed below $E_F$.

In conclusion, these results suggest that the Tl content plays a significant role in tuning the electronic properties of $Tl_xFe_2Se_2$ where doping effect might occur with the appropriate value of Tl concentration. In addition, the anion height shows strong control of the band topology of this material.
