Confronting GRB prompt emission with a model for subphotospheric dissipation

Why should we, and how do we, move to physical models?

Summary and conclusions

- ❖ We show fits to data with a physical model for GRB prompt emission.
- ❖ We obtain good fits to different bursts, without synchrotron radiation.
- ❖ We suggest that there is no fundamental difference between a burst typically fitted with Band and one fitted with Band+BB.
 - ❖ If a spectrum is found to be single or double peaked by fitting with Band or Band+BB depends on of how close the thermal and comptonised peaks are.

Band-like spectrum produced from Comptonisation of thermal component

Current and future work

- ❖ Currently expanding the parameter space
 - ❖ Includes synchrotron radiation
 - ❖ Changed jet properties
- ❖ Fitting large sample of GRBs
 - ❖ What fraction of GRBs can be described by this model?
- ❖ Distribution of best-fitting parameters and temporal evolution

ABSTRACT
 The origin of the prompt emission in gamma-ray bursts (GRBs) is still an unsolved problem and several different mechanisms have been suggested. Here we fit Fermi GRB data with a photospheric emission model which includes dissipation of the jet kinetic energy below the photosphere. The resulting spectra are dominated by Comptonization and contain no significant contribution from synchrotron radiation. In order to fit to the data we span a physically motivated part of the model's parameter space and create DREAM (Dissipation with Radiative Emission as A table Model), a table model for reuse. We show that this model can describe different kinds of GRB spectra, including GRB 090902B, representing a typical Band function spectrum, and GRB 100724B, illustrating a double peaked spectrum, previously fitted with a Band + blackbody model, suggesting they originate from a similar scenario. We suggest that the main difference between these two types of bursts is the optical depth at the dissipation site.

Key words: gamma-ray burst: general – radiation mechanisms: thermal – gamma-ray burst: individual: GRB 090902B – individual: GRB 100724B

1 INTRODUCTION
 For decades, the prompt γ -ray spectra of gamma-ray bursts (GRBs) have been fitted with the empirical Band function (Band et al. 1993). Although often producing good fits to GRB spectra, the model does not represent any physical scenario. In order to extract physical information from the observations we need to introduce physically motivated models and fit them to data.
 There are several reasons why such models should include emission from the jet photosphere: (i) Synchrotron radiation fails to explain the observed GRB spectra due to the line of death (Preece et al. 1998) and spectral width (Axelson & Burgess 2013); (ii) Some GRBs have spectra which are close to pure Planck functions (Ryde 2004; Ghirlanda, Puccetti & Ghisellini 2013; Larsson, Ryde & Burgess 2015); (iii) Many GRBs are well described by models comprising a blackbody (BB) and an additional component (Ryde et al. 2010; Goriely et al. 2011; Axelson et al. 2012; Burgess et al. 2014).
 At the same time, most bursts produce spectra not consistent with the simplest version of photospheric emission: in general the low-energy slope is far too soft to be accounted for by a BB. However, it has been realized that
